

# Supportive Evidence Document: ANTIHYPERTENSIVE AGENTS IN ADPKD

## Introduction

Due to the risks of cardiovascular complications and renal progression associated with hypertension in ADPKD, it is important to treat to blood pressure (BP) targets with appropriate therapies. Further information about BP targets is outlined in the “Blood Pressure Monitoring and Targets in ADPKD” Supporting Document.

Although non-pharmacological measures for BP control have not been specifically studied in ADPKD patients, they remain an important component of BP therapy. These include regular exercise, weight loss, smoking cessation, and sodium restriction. A multidisciplinary approach is key to provide optimal education about these measures.

However, antihypertensive agents are often necessary to reach BP targets in ADPKD patients. The magnitude of benefit of antihypertensive agents on cardiovascular and renal outcomes may differ depending on the class used. In addition, concerns with the effects of certain antihypertensive classes on disease progression have been outlined in numerous expert reviews (1-3).

## Summary of the Evidence

A summary of published clinical studies involving antihypertensives in ADPKD is provided in [Table 2](#).

## Angiotensin-Converting Enzyme (ACE) Inhibitors or Angiotensin Receptor II Blockers (ARBs)

The renin-angiotensin-aldosterone system (RAAS) appears to play a large role in the pathogenesis of hypertension in ADPKD (1). It is thought that the compression of renal cysts on renal vasculature stimulates RAAS (1). This leads to increased angiotensin II, which not only increases BP, but also acts as a growth factor for cyst growth (1). Accordingly, RAAS blockade with ACE-inhibitors or ARBs is generally considered to be first-line therapy (1). This is in line with all published guidelines and expert reviews that provide recommendations for BP management in ADPKD, as indicated in [Table 1](#).

Due to the general consensus that RAAS blockade is the cornerstone of BP management in ADPKD, the majority of studies evaluating antihypertensives have compared RAAS blockade with other antihypertensive classes (1), and select studies are summarized in the subsequent antihypertensive class sections below.

Only one study randomized patients to RAAS blockade or no RAAS blockade specifically in the ADPKD population, and this was done in 57 young patients aged 4-21 years who were either normotensive with severe ADPKD or borderline hypertensive (4). Patients were randomized to enalapril (or losartan if enalapril was not tolerated) or to treatment with no ACE-inhibitor to reach a target BP of  $\leq 50$ th or  $\leq 90$ th percentile (4).

After 5 years, there were no significant differences in renal volume, microalbuminuria, or left ventricular mass index between groups (4). A mild decline in CrCl from baseline was found in the no ACE-inhibitor treatment group, while no significant change was found in the ACE-inhibitor group (4). No safety data was reported. This study was limited by its lack of blinding, small sample size, and high dropout rate. Furthermore, the patients included in this trial were not hypertensive, and the results may have been different had the trial been conducted in a hypertensive population.

To our knowledge, there have been no clinical studies published that compare RAAS blockade to placebo or to no treatment specifically in the adult ADPKD population. A patient-level meta-analysis by Jafar et al. pooled 142 ADPKD patients (mean age 48 years) from 8 studies that compared ACE-inhibitors to any other antihypertensive agent in nondiabetic CKD patients (5). The agents included in the “control group” of the meta-analysis were: placebo, nifedipine, atenolol/acebutolol, and “not specified” (5). ACE-inhibitors were shown to be more effective in reducing proteinuria compared to the control group (5). ACE-inhibitors were also found to be associated with a lower risk of kidney disease progression, defined as a composite of doubling of baseline serum creatinine or onset of kidney failure; however, the relative risk was non-significant (RR 0.73, 95% CI 0.41-1.29) (5). Tests for interaction revealed that ACE-inhibitors had a greater effect on lowering proteinuria and slowing disease progression in patients with higher baseline proteinuria (5). Of note, the mean protein excretion of patients included in this meta-analysis was 0.92 g/day, which is higher than the level usually seen in the ADPKD population (5). In addition, due to the diversity of agents included in the control group, the results of this study are difficult to interpret.

The issue of whether ACE-inhibitors or ARBs should be preferred in ADPKD was evaluated in two small studies of 32 and 20 adult ADPKD patients (6-7). Both were

12-month, prospective, randomized trials (6-7). When comparing the ACE-inhibitor and ARB treatment groups, neither study found any difference in renal function (CrCl or eGFR) at the end of 1 year (6-7). There were also no differences between groups with regards to BP control or left ventricular mass index, which were outcomes that were evaluated in one of the studies (6). Although ACE-inhibitors and ARBs appear to have similar effects, ACE-inhibitors are more frequently used in studies. In addition, a Markov-state decision model in one study suggested that, compared to ARBs, ACE-inhibitors are more cost-effective and prolong survival by 1.39 years (8).

The safety of RAAS blockade has not been well-reported in ADPKD studies. However, as in the general population, the risks of hyperkalemia and acute kidney injury are important considerations.

## Combination of ACE-inhibitors and ARBs

HALT-PKD Study A and Study B were two large, randomized, double-blind, placebo-controlled studies that compared the combination of ACE-inhibitor and ARB (lisinopril and telmisartan), versus an ACE-inhibitor alone (lisinopril and placebo) (9-10). Study A was conducted in patients with early ADPKD, and the primary outcome was annual percentage change in total kidney volume (9). Study B was conducted in patients with late ADPKD, and the primary outcome was the composite of time to death, end-stage renal disease, or a 50% reduction from baseline eGFR (10).

In both studies, the rates of adverse events were low and similar between the two groups; however, no benefit of dual RAAS blockade was found over the ACE-inhibitor alone (9-10).

Dual RAAS blockade with ACE-inhibitors and ARBs is therefore not recommended for BP management in ADPKD patients, and this has been indicated in a

number of guidelines and expert reviews (3, 11-12).

## Diuretics

Increased aldosterone levels and associated sodium retention are thought to contribute to the pathogenesis of hypertension in ADPKD patients (1). Consequently, diuretics, which promote sodium excretion, have been considered to be reasonable second- or third-line agents by numerous experts (1-2, 11, 13). However, there is also a concern that diuretics may increase RAAS activation through volume depletion, leading to increased ADPKD progression. Cautious use has therefore been recommended in a couple expert reviews (1, 3).

Only one prospective study examining clinical outcomes with diuretics has been published. This was a historical, single-center prospective, non-randomized study of 33 hypertensive ADPKD patients who were followed for a mean of 5.2 years (14). Patients who were taking diuretic(s) without an ACE-inhibitor were compared to those taking an ACE-I without any diuretics (14). Although BP control was similar between groups, the decline from baseline and annual decline in CrCl was significantly higher in the diuretic group (14). In addition, urinary protein excretion increased significantly from baseline in the diuretic group, while no significant change was seen in the ACE-inhibitor group (14). Plasma sodium and potassium remained stable in both groups (14), and no other safety data was provided. However, all patients were taking ACE-inhibitors or diuretics at baseline, and it is therefore likely that they were already tolerating these agents. This study was limited by its small sample size and non-randomized design. In addition, the diuretic group had higher diastolic BP, lower CrCl, and higher urinary protein excretion at baseline, which may have contributed to the results.

To summarize, the concern that diuretics worsen

ADPKD progression is only theoretical at this time. Because no studies have been published comparing diuretics to placebo or to no treatment, there is currently no data to inform on whether diuretics have any detrimental effect on ADPKD progression. In addition, one low-quality study suggested that diuretics are inferior to ACE-inhibitors for renal outcomes, but further studies are needed to confirm this finding.

## Calcium Channel Blockers (CCBs)

Cyclic AMP (cAMP) is responsible for cyst cell proliferation in ADPKD, and it is thought that cAMP's effects in this condition are mediated by reduced intracellular calcium levels (1). There is a concern that blockade of calcium entry into renal cells by CCBs may worsen ADPKD progression (15), and cautious use has been recommended in a few expert reviews (1-3). This concern has been supported by a study in which verapamil was tested on ADPKD rats (15). Compared to control-treated rats, those that were administered verapamil had greater renal cell proliferation and apoptosis, kidney weight, and cyst index (15).

To our knowledge, there have been no clinical trials comparing CCBs to placebo or to no treatment in humans. In addition, there have been no clinical trials evaluating the effects of non-dihydropyridine CCBs compared to other antihypertensives.

Four clinical trials have been conducted to compare the effects of dihydropyridine CCBs to those of RAAS blockade in ADPKD, and they have yielded mixed results (16-19). The only trial with results favoring CCB therapy was a study by Kanno et al., which found that amlodipine was associated with a significantly lower reduction in CrCl from baseline when compared to enalapril after 2 years (16). A sub-analysis of a 7-year study by Schrier et al. showed no significant difference in 24-hour CrCl when comparing patients who received enalapril or amlodipine for at least 80% of the study

duration (17). In contrast, two studies concluded that CCBs were associated with worse outcomes when compared to ACE-inhibitors or ARBs (18-19). In the first study by Ecker et al., the annual mean decline in CrCl was higher in the amlodipine group compared to the enalapril group (annual mean decline of 4.2 mL/min/1.73 m<sup>2</sup> vs. 2.8 mL/min/1.73 m<sup>2</sup>); however, the difference between groups did not meet statistical significance (18). In addition, a significant decrease in albumin-to-creatinine ratio was seen in the enalapril group, while proteinuria remained stable in the amlodipine group (18). The albumin-to-creatinine ratio was significantly higher in the amlodipine group at the end of the study (18). Similarly, in a 3-year study by Nutaraha et al., amlodipine was compared to candesartan and was associated with a significantly greater decline in CrCl, as well as a significantly higher degree of proteinuria (19). All of the four aforementioned studies were limited by very small sample sizes, which ranged from 24 to 69 patients (16-19). In addition, in the study by Nutaraha et al., many of the patients had missing data at various timepoints during the study, including at baseline (19).

Three retrospective studies have also provided evidence that CCBs may be associated with worse outcomes compared to RAAS blockade, though not all studies included information on whether the CCBs were within the dihydropyridine or non-dihydropyridine classes. In a small study by Mitobe et al., rate of eGFR reduction was positively associated with dihydropyridine CCB therapy, but not RAAS blockade therapy, after a mean treatment duration of 2.4 years (20). Furthermore, a retrospective study by Orskov et al. found that both CCBs and RAAS blockade were associated with a later onset of end-stage renal disease (ESRD) (21). The two classes were not compared directly, but results were more favorable with RAAS blockade (4.3 delay in onset of ESRD with RAAS blockade, vs. 2.1 years with CCB) (21). Finally, in a study by Patch et al., RAAS blockade and CCB prescriptions were independently associated with lower mortality,

but the incident rate ratio was somewhat lower with RAAS blockade [0.53 (95% CI 0.35-0.80) with CCBs, vs. 0.44 (95% CI 0.17-0.42) with RAAS blockade] (22). These studies were limited by their retrospective designs, and it is likely that the analyses did not adjust for all potential confounders.

Limited or no safety data was reported in all of the aforementioned studies.

In summary, the concern that CCBs lead to accelerated ADPKD progression is theoretical at this time. No studies have been published comparing CCBs to placebo or to no treatment, and there is therefore currently no data to inform on the effects of CCBs on ADPKD. Studies comparing CCBs to RAAS blockade are of low-quality, but they collectively suggest that CCBs are associated with worse outcomes.

## Beta-Blockers

Due to the theoretical concerns with diuretics and calcium channel blockers that are outlined above, beta-blockers have been recommended as second-line agents in a number of expert reviews (2-3, 13).

Two published studies have evaluated clinical outcomes with beta-blockers in hypertensive ADPKD patients (23-24). In the first study by van Dijk et al., 28 hypertensive ADPKD patients completed a 3-year trial in which they were randomized to enalapril or atenolol (up to a maximum dose of 20 mg/day and 100 mg/day, respectively) (23). In the second study by Zeltner et al., 37 hypertensive patients completed a 3-year trial in which they were randomized to ramipril or to metoprolol (up to maximum dose of 5 mg/day or 100 mg/day, respectively) (24). In both studies, no significant differences were found in mean arterial pressure, decline in eGFR, or change in albumin-to-creatinine ratio when comparing the ACE-inhibitor and beta-blocker groups (23-24). In addition, no significant

difference in left-ventricular mass index was found in the study by Zeltner et al. (24). Very limited safety data were provided in both of these studies. The trials were limited by their small sample sizes and by the low doses of ACE-inhibitors used. The maximum dose of metoprolol used in the study by Zeltner et al. was also lower than typically recommended.

In summary, limited and very low-quality data suggest that beta-blockers have similar effects on renal outcomes compared to ACE-inhibitors in ADPKD. Further studies are needed to confirm this finding.

## Other Antihypertensives

To our knowledge, there have been no published studies evaluating other commonly-used antihypertensives (e.g. alpha-blockers, direct vasodilators) in ADPKD.

## Choice of Antihypertensive(s) in BP Management

With the exception of the use of RAAS blockade as first-line therapy, antihypertensive regimens employed in ADPKD studies have varied widely.

The best evidence to inform on BP management in ADPKD is HALT-PKD Study A, which randomized 558 hypertensive patients aged 15-49 years of age with an eGFR > 60 mL/min/1.73 m<sup>2</sup> to a standard or low BP target and to either ACE-inhibitor/ placebo or an ACE-inhibitor/ARB combination (9). 2nd-, 3rd-, and 4th-line antihypertensives were respectively: hydrochlorothiazide; metoprolol; and non-dihydropyridine CCBs, clonidine, minoxidil, and/or hydralazine (9).

Compared to the standard BP target group, patients in the low BP target group had a significantly lower annual percentage increase in total kidney volume,

a similar overall change in eGFR, a greater reduction in left ventricular mass index, and a greater reduction in urinary albumin excretion (9). Dizziness and lightheadedness were also more common in the low target BP group (9). This study therefore provided evidence that targeting a lower BP in young patients with preserved renal function is effective in slowing ADPKD progression.

The proportions of patients who used certain antihypertensives were much greater in the low BP target group compared to the standard BP target group (9). These antihypertensives included diuretics (44.9% vs. 26.8%, p<0.001) and beta- or alpha/beta-blockers (31.4% vs. 14.4, p<0.001) (9). This suggests that the addition of diuretics and/or beta-blockers to RAAS blockade may be effective in reducing ADPKD progression through improved BP control.

The proportion of patients who used CCBs was also significantly greater in the low BP target group compared to the standard target BP group (10.2% vs. 5.3%, p<0.001) (9). However, the proportions of CCB-users were small in both arms. It is therefore less likely that CCBs contributed to the better outcomes seen in the low BP target group.

## Statements/Recommendations

- RAAS blockade with ACE-inhibitors or ARBs is generally recommended as first-line therapy for hypertension in ADPKD patients.
  - This recommendation is based on the postulation that RAAS activation plays a major role in the pathogenesis of hypertension in ADPKD.
  - There is limited evidence to support that RAAS blockade is superior to other antihypertensive classes for reducing ADPKD progression.
    - However, findings from low-quality studies collectively do suggest that CCBs

are associated with more rapid decline in renal function compared to RAAS blockade.

- Compared to other antihypertensive classes, RAAS blockade may be more effective in reducing proteinuria; however, the clinical relevance of proteinuria reduction in ADPKD is unclear.
- ACE-inhibitors have been most commonly used than ARBs in studies and are the preferred first-line agents, but ARBs may be used if ACE-inhibitors are not tolerated.
- Based on the HALT-PKD studies, there is no role for dual RAAS blockade with an ACE-inhibitor and ARB.
- There are concerns that diuretics and CCBs may increase ADPKD progression based on their mechanisms of action. However, due to the absence of studies comparing them to placebo or to no treatment, there is currently no data to inform on whether these agents are harmful.
- There is limited data available to guide the choice of antihypertensive if RAAS blockade is not tolerated or if additional antihypertensive(s) are needed to achieve BP targets.
  - Due to the theoretical concerns about diuretic and CCB use in ADPKD, some experts suggest beta-blockers as the second-line agent of choice. However, there is limited data to support this.
  - In HALT-PKD Study A, thiazide diuretics and beta-blockers were added to RAAS blockade as second- and third-line agents, respectively. For patients who meet HALT-PKD Study A inclusion criteria (15–49 years old with eGFR > 60 mL/min/1.73m<sup>2</sup>), this may be a reasonable approach until further data is available.
- In all cases, antihypertensive regimens should be individualized. Considerations when making decisions about regimens should include the presence of comorbidities that are indications for specific antihypertensives, medication side effect

profiles, CKD stage, and pill burden.

Review Article	Fall and Prisant (7)	2005	<ul style="list-style-type: none"> <li>• “[Blood pressure] treatment should include the use of angiotensin-converting enzyme inhibitors.”</li> </ul>
	Sans-Axter et al. (8)	2013	<ul style="list-style-type: none"> <li>• “Even though a nonpharmacological approach should not be neglected, RAAS inhibitors are the cornerstone of hypertension treatment.”</li> <li>• “...both dihydropyridine and non-dihydropyridine CCBs should probably be avoided as first- and probably second-line treatment in patients with ADPKD. However, considering that ADPKD patients show resistant hypertension and CCBs are good antihypertensive drugs, they should certainly be third-line treatment”</li> <li>• “Because aldosterone levels are greater in hypertensive ADPKD patients than in essential hypertensives, and higher aldosterone levels may lead to sodium retention, diuretics should be considered as second-line treatment in hypertensive ADPKD. It must be noted, however, that diuretic treatment may lead to extra activation of the RAAS owing to volume depletion. In hypertensive ADPKD patients with normal renal function, thiazide diuretics are the first choice. In those with impaired renal function and glomerular filtration rate &lt;30 mL/min/1.73 m<sup>2</sup>, long-acting loop diuretics must be the first choice.”</li> <li>• “To our knowledge, other drug treatments (e.g. alpha-blockers, direct vasodilators) have not been compared with RAAS inhibitors and may play a secondary role in hypertension treatment in this population.”</li> </ul>
	Rangan et al. (9)	2016	<ul style="list-style-type: none"> <li>• “[Hypertension] is mediated by increased intra-renal angiotensin II production in cystic epithelial cells... Hence, angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers are the preferred first-line meds.”</li> </ul>
	Krishnappa et al. (10)	2017	<ul style="list-style-type: none"> <li>• “Early diagnosis and aggressive management of high blood pressure, specifically with meds that block the renin-angiotensin-aldosterone system, are necessary to prevent left ventricular hypertrophy and progression of renal failure in ADPKD.”</li> <li>• “ACE inhibitors are first-line drugs in hypertensive ADPKD patients.”</li> <li>• “ARBs can be considered, but there is no role for dual ACE inhibitor and ARB therapy. A study found ACE inhibitors to be more cost-effective and to decrease mortality rates to a greater extent than ARBs.”</li> <li>• “Beta-blockers or calcium channel blockers should be considered instead if ACE inhibitors and ARBs are contraindicated, or as add-on drugs if ACE inhibitors and ARBs fail to reduce blood pressure adequately.”</li> <li>• “Diuretics are third-line meds. Thiazides are preferred in ADPKD patients with normal renal function and loop diuretics in those with impaired renal function.”</li> </ul>

- “...an ACEI or ARB should be the initial antihypertensive med... Patients who develop a significant decline in renal function may be more safely treated with another med such as a beta-blocker or calcium channel blocker; we prefer to use a beta blocker as a second med given the potentially detrimental effects of calcium blockers on cyst formation.”
- “Diuretics, used in conjunction with inhibitors of the RAAS, may be effective in reducing BP in
- ADPKD patients, particularly those with established CKD where the capacity to excrete sodium is reduced, and BP is maintained through intravascular volume expansion. In hypertensive ADPKD patients with normal kidney function, thiazide diuretics are the first choice. In those with impaired kidney function, long-acting loop diuretics must be the first choice. Diuretics should be considered as second- or third-line treatment in hypertensive ADPKD.”
- “To the best of our knowledge, alpha blockers and direct vasodilators have not been tested and compared with RAAS inhibitors in ADPKD population.”
- Suggested treatment algorithm:

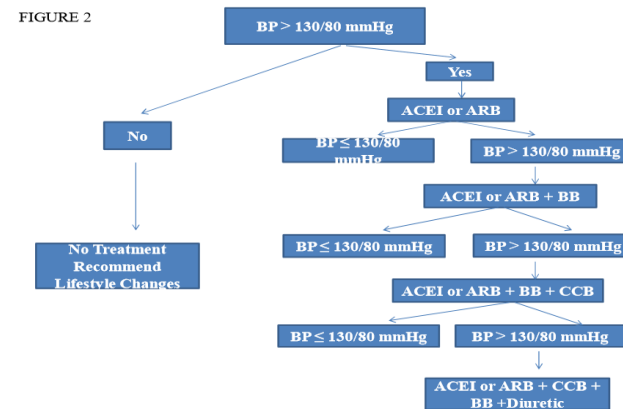

Figure 2. Treatment algorithm of hypertension in ADPKD. ADPKD: Autosomal dominant polycystic kidney disease, ACEI: Angiotensin-converting enzyme inhibitor, ARB: Angiotensin receptor blockers, CCB: Calcium channel blockers, BB: β-Blockers, BP: Blood pressure.

	Chebib et al. (12)	2018	<ul style="list-style-type: none"> <li>• “Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers increase kidney blood flow at early stages of the disease and are the first-line therapy for ADPKD.”</li> <li>• “Dual renin-angiotensin blockade had no beneficial effect compared with ACE inhibition alone.”</li> <li>• “It is not clear which antihypertensive drug class should be used as second line. Combined <math>\alpha/\beta</math> blockers have good metabolic and hemodynamic profiles and are well tolerated. <math>\beta</math>-blockers or <math>\alpha</math> 1 adrenergic antagonists are preferred for patients with comorbid conditions, such as angina or benign prostatic hyperplasia.”</li> <li>• “Calcium channel blockers and diuretics should be used cautiously because of hypothetical concerns that they might worsen disease progression.”</li> <li>• “By order of preference:             <ol style="list-style-type: none"> <li>1. ACEI/ARB</li> <li>2. <math>\alpha/\beta</math> or cardioselective <math>\beta</math>-blocker</li> <li>3. Dihydropyridine CCB</li> <li>4. Diuretic”</li> </ol> </li> </ul>
